This paper proposes an adaptive variant of Random Early Detection (RED) gateway queue management for packet-switched networks via a discrete state analog of the non-stationary Master Equation i.e. Markov process. The computation of average queue size, which appeared in the original RED algorithm, is altered by introducing a probability $P(l, t)$, which defines the probability of having l number of packets in the queue at the given time t , and depends upon the previous state of the queue. This brings the advantage of eliminating a free parameter: queue weight, completely. Computation of transition rates and probabilities are carried out on the fly, and determined by the algorithm automatically. Simulations with unstructured packets illustrate the method, the performance of the adaptive variant of RED algorithm, and the comparison with the standard RED.

I. INTRODUCTION

Dynamics in the self-driven, many particle systems have been related to traffic flow problems, and attracted the interest of many different disciplines [1]. Traffic breakdown in these systems is a prominent example. These studies mostly focused on jams of freeway traffic. Similar approaches have been taken along these lines for congestion avoidance in computer networks, especially congestion control on the Internet. Techniques of mathematical and statistical physics are suitable and applicable, since these problems have universal dynamics [2, 3].

Congestion avoidance, or control, aims at preventing the dynamic breakdown of the traffic and insuring a fair sharing of resources. For the case of packet-switching networks, bottlenecks may frequently occur in gateways. Previous studies, that addressed congestion avoidance in gateways, have focused on mechanisms which keep throughput high and average queue size low. Some of these mechanisms are designed to work with gateways or coupled to gateway scheduling algorithms [4].

The most notable and widely used algorithm is Random Early Detection (RED) gateways [5]. The primary mechanism that RED provides, allows queue size growth as long as a statistical probability measure is satisfied, otherwise incoming packets are dropped. In this way the gateway adjusts queue buffer space for fair traffic share. Dynamics of congestion control models and RED gateways were rigorously investigated under different settings in the large literature on the subject, We follow a different path and present a direct adaptive variant to the original RED algorithm with new interpretation of the state of the queue, which is characterised by its length, is coupled with a Master Equation.

II. A MASTER EQUATION RED

The investigation of many physical time-dependent processes starts with the statistical description based on well studied generalised Master Equation [6].

The discrete state analog of the Master Equation as a differential difference equation in one-dimension is

$$\begin{aligned} dP(l, t)/dt = & a_{l, l+1}P(l+1, t) + a_{l, l-1}P(l-1, t) - \\ & (a_{l-1, l} + a_{l+1, l})P(l, t) \end{aligned} \quad (1)$$

where $P(l+j, t)$ is the probability that the system is in the state $(l+j)$ at time t and where $a_{l, j}$ are the transition rates from state j to l . Addressing the theory behind Master Equation goes beyond the scope of the present study.

In the original RED algorithm, the computation of instantaneous average queue size, avg , is determined dynamically by an exponential weighted moving average when the queue is non-empty

$$avg = (1 - w_q)avg + w_q q$$

where w_q is the queue weight, a free parameter, and q is the current queue size .

The primary method in the Master Equation Random Early Detection (mRED) algorithm is interpreting probability evolution $P(l, t)$ as the probability of having l number of packets in the queue at given time t . This probability comes into play in finding the average queue size, avg , where q is the current queue size at time t

$$avg = qP(q, t) \quad (2)$$

Next, $a_{l,j}$ is the transition rate from state j to l , which determined by using free energy [6] of a given state. Here, the free energy measure is taken to be an absolute of sum of aimed queue length and average queue length in the previous state. Hence, forward or backward transition rates are computed as follows

$$a_{j,l} = \exp(-|j + avg|) \quad (3)$$

since we are in Markov regime, j can only take values $l + 1$ and $l - 1$, for forward and backward rates respectively. The average queue size plays an important role here, namely the information from the previous state of the queue. This value changes at each time step, so one needs to update all probabilities and the transition rates accordingly. The exponential in the transition rates is a reminiscent of the Boltzmann factor of Statistical Physics.

As an illustrative example. If 6 and 4 were forward and backward queue length, 5 is the current queue size, and if avg is 0.3, then simply symmetric transition rates will be $a(5,6)=0.0049$ and $a(6,5)=0.0018$. However, the following ratio between symmetric index rate constants is valid at the *weak detailed balance* condition (when system is at near equilibrium)

$$a(j, j - 1)/a(j - 1, j) = \exp(-\Delta E) \quad (4)$$

ΔE is the energy difference between states j and $j - 1$. Since, the measure of energy in queue system is expressed with the avg and the current queue length. Ideally ΔE should be zero, if current queue length j or its neighbors near it are in the optimal value, analogy with a minimum. The energies in a given transition $j \rightarrow j - 1$ or $j - 1 \rightarrow j$ expressed as exponential of the starting state plus the average queue length, $\exp(-|j + avg|)$ and $\exp(-|j - 1 + avg|)$, respectively. And, the only condition to make this ratio 1, is when $j - 1$ or j approaches the value of average queue size. So actually, imposing the condition in the eq. 4 is to drive the current queue length to average queue length.

The *weak detailed balance* condition, that ΔE should be zero, impose an other condition,

$$a(j, j - 1)/a(j - 1, j) = a(j, j + 1)/a(j + 1, j) \quad (5)$$

So imposing this condition implies we can take as the following rates equal, $a(j, j - 1) = a(j, j + 1)$. Important point is we do not take eqns 4 and 5 directly in solving master equations rather, we would like to drive the queue behaviour into this conditions. Moreover, this type of formulations is intrinsically phenomenological and constructed with making analogy with the queue behaviour as an approximation.

Implementation of mRED must follow the same path as RED with the different computation strategy for the average queue size. This can be achieved by solving the differential difference Master Equation numerically on every packet arrival or on specified time intervals. The frequency of updating transition rates and probabilities can be decided. In our implementation, we solved the equation on every packet arrival with the information of current queue size. The general algorithm for mRED is given

```

for each packet arrival
  Update the set of transition rates using
    previous average queue size
  Solve numerically the set of Master Equations
    for all probability values  $P(l,t)$ 
  Calculate the average queue size by using  $P(q,t)$ 
  if  $minth \leq avg < maxth$ 
    Calculate marking probability
    with marking probability :
      mark the arriving packet
  else if  $maxth \leq avg$ 
    mark the arriving packet

```

If the buffer size is N , including the zero size queue, then one needs to store, $2N - 2$ number of transition rates and N number of probability values (because one needs to know forward and backward transition rates for N state, zero to buffer size, but for queue size zero there is no backward transition rate and for queue size N there is no forward transition rate, so mRED needs to store and update $2N - 2$ transition rates). All values can be initialised randomly, and the procedure updates the values in response to previous behaviour of the queue.

Let us remember that the current queue size is q . The probability of having q packets in the queue at the current moment is extracted as follows. First, a number of N probabilities : $P(0,t), P(1,t), \dots, P(N,t)$ are computed solving the Master equation. Then, knowing the current queue size q , we extract $P(q,t)$ from the list.

III. SIMULATIONS

Simulations were carried out with a simulation package, that we have developed [7]. Two different network settings have been simulated, where some of the original parameters reported in [5] were used. Those are threshold values $minth = 5$ and $maxth = 15$, for minimum and maximum queue threshold respectively and $maxp = 1/50$, the threshold for marking probability (marked packets are dropped by the gateway). We first studied a network for which the highest possible packet arrival is slightly higher than the maximum queue threshold ($maxth$). Next, we investigated a network with bursty traffic where the highest packet arrival rate can be as high as 3 times the maximum queue threshold.

The initial step in setting up the network is assigning a number of hosts that generated the packets to the gateway. At each time step, randomly selected hosts were sending packets that were processed by the queue management system. If the packet is marked for drop, the corresponding host gets the drop contribution. The Master Equation routine is invoked whenever the average queue size, avg , was needed and the current queue size q , was provided to the algorithm. First, transition rates are computed for all the possible queue sizes, from zero size to buffer size, following the same notation (for $a_{l,j}$ values, indexes correspond to each other in the following way, $j = 1, \dots, N - 1$ and $l = 2, \dots, N$ for forward transitions, and $j = 2, \dots, N$ and $l = 1, \dots, N - 1$ for backward transitions, respectively). Afterwards, all possible queue size probabilities are computed by solving a Master Equation numerically (Forward Euler Method) for a later time with small enough Δt

$$\begin{aligned}
 P(l, t + \Delta t) = & (a_{l,l+1}P(l+1, t) + a_{l,l-1}P(l-1, t) - \\
 & (a_{l-1,l} + a_{l+1,l})P(l, t))\Delta t + P(l, t)
 \end{aligned} \tag{6}$$

Hence, the probability of having current queue size q is returned back to the main mRED routine to compute the current average queue size.

Here, the buffer size was big enough to prevent any drops due to buffer overflow. The packet drop rates do not depend upon the buffer size. But, buffer size plays an important role in updating probabilities in mRED. It determines the propagation of probability values. Remember that any probability value $P(l, t)$ also depends upon $P(l-1, t)$ and $P(l+1, t)$. In this sense, the number of possible different queue length must be large enough to have a better statistics for probability values. For that reason we choose the value $N = 500$ as a test case which is not too small. All the results reported used this value for the buffer size N .

We have used a time step of $\Delta t = 0.01$ which gives sufficiently accurate results for testing purposes. We have used 6 hosts connected to a gateway in two different network traffic conditions. Network 1 and 2 have assigned the following packet rates per unit time for hosts, (2, 3, 2, 1, 6, 4) and (14, 7, 4, 5, 12, 3), and the maximum possible rate of 18 and 45, respectively.

FIG. 1: The total traffic and packet drop for both sample Network 1 and 2. The relative traffic utilisation drawn from this data, one minus the ratio of total drop to total traffic. Simulation carried on 10000 steps. Here only a portion is shown. Network 2 mimics heavily congested traffic situation.

IV. DISCUSSION

The comparison of total traffic and drops for every step are reported in Figure 1. We can see that behaviour of both mRED and RED is quite similar. This is an important point, because it reflects and hints that mRED do not introduce any artifact on the original design of RED. The traffic performance of mRED must be compared with the proposed adaptive RED [8], which removes other two threshold parameters. Moreover mRED can be combined with adaptive RED [8], which such a scheme will remove all the free parameters. These points must be address in a future study.

Introduction of an arbitrary discrization time step changes the smoothing time-scale. This can be overcome by choosing smaller time intervals for the Master Equation solver, such as orders of milliseconds. In practice millisecond is the conventional time-scale in packet-switched networks. Also, time interval is hidden in computation of transition rates in the formulation we have used, and it must be introduced for real-time implementations.

The computational performance of mRED algorithm depends on the buffer size, not to confuse with the traffic performance measured with relative traffic utilisation. The implementations issues are not the scope of the current paper but a simple analysis hints feasibility of implimentation. While number of algebraic operations for solving master equations grow linearly with the queue buffer size. For example a rough estimate of brute force implementation of mRED can be sketch as follows. Assuming buffer size of 2000 which is 20 times larger then a typical router packet buffer, then, the total operations needed for whole mRED is 43 986, which is about ~ 5 KFLOPS. This number of operation can be handled with modern processor like x86 in couple of milliseconds or less (assuming that processor can handle more then 2 MFLOPS). Moreover memory requirement is only about ~ 100 KB for whole procedure, and grows linearly with increasing buffer size.

V. CONCLUSION

The primary advantage of using Master Equation is the elimination of the queue weight parameter w_q . This is clearly a desirable and beneficial approach under circumstances where determination of w_q is not straight forward. However, the further investigation of mRED's behaviour and its comparison with adaptive RED [8] is needed, by using real packets and protocol environment, such as TCP and FTP.
